Targeting Prices or Nominal GDP: Forward Guidance and Expectation Dynamics*

by

Seppo Honkapohja, Bank of Finland
Kaushik Mitra, University of Birmingham

Date: February 26, 2015

Abstract

We examine global dynamics under learning in New Keynesian models where monetary policy practices either price-level or nominal GDP targeting and compare these regimes to inflation targeting. The interest-rate rules are subject to the zero lower bound. The domain of attraction of the targeted steady state is proposed as a new robustness criterion for a policy regime. Robustness of price-level and nominal GDP targeting depends greatly on whether forward guidance in these regimes is incorporated in private agents’ learning. We also analyze volatility of inflation, output and interest rate during learning adjustment for the different policy regimes.

JEL Classification: E63, E52, E58.

* Earlier versions (with slightly different title "Targeting Prices or Nominal GDP: Guidance and Expectation Dynamics") were presented in workshops organized by San Francisco Federal Reserve Bank, CDMA Saint Andrews, University of Pavia, Heriott-Watt University, MMF 2014 conference, and in various seminars. We are grateful for useful comments by Klaus Adam, James Bullard, George W. Evans, Bruce Preston, John Williams, and the workshop and seminar participants. Any views expressed are those of the authors and do not necessarily reflect the views of the Bank of Finland.
I. Introduction

The practical significance of the zero lower bound (ZLB) for policy interest rates has become evident in the US and Europe since the 2007-9 financial crisis and in Japan since the mid 1990s. In the monetary economics literature the Japanese experience initiated renewed interest in ways of avoiding or getting out of the ZLB constraint. During the ongoing economic crisis some new tools have been added to monetary policy. One of them, forward guidance, has been widely used. Forward guidance is often made using announcements of plans about the instruments of monetary policy - most commonly the policy interest rate. However, forward guidance may also be in terms of a threshold for a target variable, such as the price level or nominal GDP, so that the interest rate is kept at the ZLB until the actual value of the target variable reaches its threshold level, for example see (Woodford 2012), pp. 228-30 and (Mendes and Murchinson 2014).

A key part of price-level (nominal GDP, respectively) targeting is the announcement of a future target path for the price level (nominal GDP, respectively) that provides the threshold triggering a change in the policy instrument. There are recent suggestions that price-level or nominal GDP targeting can be more appropriate frameworks for monetary policy than inflation targeting. (Carney 2012) and (Evans 2012) discuss the need for additional guidance for the price level and possibly other variables including the nominal GDP. (Carney 2012) suggests that with policy rates at ZLB “there could be a more favorable case for nominal GDP targeting”. (Evans 2012) argues that price-level targeting might be used to combat the liquidity trap. Price-level or nominal GDP targeting makes monetary policy history-dependent. This can be helpful and is arguably good policy in a liquidity trap where the ZLB constrains monetary policy. See (Eggertsson and Woodford 2003) for a discussion of optimal monetary policy and a modified form of price-level targeting under rational expectations (RE).

If, say, a move from inflation targeting to either nominal income or price-level targeting is contemplated, it is important to allow for the possibility that private agents face significant uncertainties when a new policy regime is adopted. We consider the properties of price-level and nominal
GDP targeting under imperfect knowledge and learning where the latter is described by the adaptive learning approach which is increasingly used in the literature. In this approach for each period agents maximize anticipated utility or profit subject to expectations that are derived from an econometric forecasting model given the data available at that time and the model is updated over time as new information becomes available.\(^5\) Our approach contrasts with the existing literature on nominal income and price-level targeting that is predominantly based on the RE hypothesis. RE is a very strong assumption about the agents’ knowledge of the economy. We note that there has recently been increasing interest in relaxing the RE hypothesis in the context of macroeconomic policy analysis, see e.g. (Taylor and Williams 2010), (Woodford 2013) and (Eusepi and Preston 2015).\(^6\)

Our objective is to compare several aspects of dynamics of price-level and nominal income targeting to inflation targeting in a standard nonlinear New Keynesian (NK) model when private agents learn adaptively. For concreteness, it is assumed that the agents do not know the interest rate rule even though the target path or variable is known. We compare the three policy frameworks in the simplest setting that is free from financial market problems. The full nonlinear framework is needed to assess the global properties of these targeting regimes, including hitting to the ZLB.

A preliminary result is that, like inflation targeting, nominal income and price-level targeting are subject to global indeterminacy problems caused by the ZLB. There are two steady states, the targeted steady state and a low-inflation steady state in which the policy interest rate is at the ZLB.

We then introduce a new criterion for assessing the robustness of monetary policy regimes by computing the size of the domain of attraction of the targeted steady state under learning for each policy regime. The criterion answers the question of how far from the targeted steady state can the initial conditions be and still deliver convergence to the target. Formally, the domain of attraction is the set of all initial conditions from which learning dynamics converge to the steady state. Intuitively, an initial condition away from the targeted steady state represents a shock to the economy and a large domain of attraction for a policy regime means that the economy
will eventually get back to the target even after a large shock.

The key result of the paper is that the dynamic performance of learning strongly depends on whether private agents include the forward guidance provided by the price-level or nominal GDP targeting regime into their expectations formation. If agents incorporate either the target price level path or the target nominal GDP path, respectively, into their inflation forecasting, the convergence properties of price-level or nominal GDP targeting are excellent. Numerical analysis indicates that under price level or nominal GDP targeting with forward guidance the economy will converge back to the targeted steady state from a very large set of possible initial conditions far away from the target. Thus the economy can gradually escape a deflationary situation created by a large pessimistic shock.

There is even convergence to the target from initial conditions arbitrarily close to the low steady state and when the ZLB is binding. The low steady state is totally unstable under learning if the policy regime is price level or nominal GDP targeting with forward guidance. The result also implies that these two policy regimes are superior to inflation targeting.

However, if agents do not include forward guidance from dynamic target paths in their forecasting, then performance of price-level and nominal GDP targeting is much less satisfactory. Without forward guidance agents form expectations using only available data on inflation and aggregate output in the same way as is natural under inflation targeting. The targeted steady state is only locally stable under learning and the deflationary steady state locally unstable for the price-level and nominal GDP targeting regimes. Numerical analysis of the domain-of-attraction criterion for the three policy regimes indicates that price-level and nominal GDP targeting without forward guidance perform worse than inflation targeting.\(^7\)

In addition to the size of the domain-of-attraction criterion, we introduce a second performance criterion, namely the magnitude of fluctuations during the learning adjustment when initial conditions are close to the targeted steady state. This is done by computing the volatilities of aggregate variables, a loss function, and ex post utilities during the learning adjustment for the different monetary policy regimes (inflation, price-level and
nominal GDP targeting with or without forward guidance).

II. A New Keynesian Model

We employ a standard New Keynesian model as the analytical framework. There is a continuum of household-firms, which produce a differentiated consumption good under monopolistic competition and price-adjustment costs. There is a government which uses monetary policy, buys a fixed amount of output, finances spending by taxes, and issues of public debt. The objective for agent $s$ is to maximize expected, discounted utility subject to a standard flow budget constraint (in real terms):

$$\text{Max } E_0 \sum_{t=0}^{\infty} \beta^t U_{t,s} \left( c_{t,s}, \frac{M_{t-1,s}}{P_t}, h_{t,s}, \frac{P_{t,s}}{P_{t-1,s}} - 1 \right)$$

subject to:

$$st. \ c_{t,s} + m_{t,s} + b_{t,s} + \Upsilon_{t,s} = m_{t-1,s} \pi_t^{-1} + R_{t-1} \pi_t^{-1} b_{t-1,s} + \frac{P_{t,s}}{P_t} y_{t,s},$$

where $c_{t,s}$ is the consumption aggregator, $M_{t,s}$ and $m_{t,s}$ denote nominal and real money balances, $h_{t,s}$ is the labor input into production, and $b_{t,s}$ denotes the real quantity of risk-free one-period nominal bonds held by the agent at the end of period $t$. $\Upsilon_{t,s}$ is the lump-sum tax collected by the government, $R_{t-1}$ is the nominal interest rate factor between periods $t-1$ and $t$, $P_{t,s}$ is the price of consumption good $s$, $y_{t,s}$ is output of good $s$, $P_t$ is the aggregate price level, and the inflation rate is $\pi_t = P_t/P_{t-1}$. The subjective discount factor is denoted by $\beta$. The utility function has the parametric form

$$U_{t,s} = \frac{c_{t,s}^{\mu_1}}{1 - \mu_1} + \frac{\chi}{1 - \mu_2} \left( \frac{M_{t-1,s}}{P_t} \right)^{1 - \mu_2} - \frac{h_{t,s}^{1 + \varepsilon}}{1 + \varepsilon} - \frac{\gamma}{2} \left( \frac{P_{t,s}}{P_{t-1,s}} - 1 \right)^2,$$

where $\mu_1, \mu_2, \varepsilon, \gamma > 0$. The final term parameterizes the cost of adjusting prices in the spirit of (Rotemberg 1982). We use the Rotemberg formulation rather than the Calvo model of price stickiness because it enables us to study global dynamics in the nonlinear system. The household decision problem is also subject to the usual “no Ponzi game” (NPG) condition. Production function for good $s$ is given by $y_{t,s} = h_{t,s}^{\alpha}$ where $0 < \alpha < 1$. 

4
Output is differentiated and firms operate under monopolistic competition. Each firm faces a downward-sloping demand curve

\[ P_{t,s} = \left( \frac{y_{t,s}}{y_t} \right)^{-1/\nu} P_t. \]

\( P_{t,s} \) is the profit maximizing price by firm \( s \), consistent with its production \( y_{t,s} \). The parameter \( \nu \) is the elasticity of substitution between two goods and \( \nu > 1 \). \( y_t \) is aggregate output, which is exogenous to the firm.

The government’s flow budget constraint in real terms is

\[ b_t + m_t + \Upsilon_t = g_t + m_{t-1} \pi_t^{-1} + R_{t-1} \pi_t^{-1} b_{t-1}, \]

where \( g_t \) is government consumption of the aggregate good, \( b_t \) is the real quantity of public debt, and \( \Upsilon_t \) is the real lump-sum tax. We assume that fiscal policy follows a linear tax rule

\[ \Upsilon_t = \kappa_0 + \kappa b_{t-1}, \]

for lump-sum taxes as in (Leeper 1991), where we assume that \( \beta^{-1} - 1 < \kappa < 1 \). Thus fiscal policy is “passive” in the terminology of (Leeper 1991) and implies that an increase in real government debt leads to an increase in taxes sufficient to cover the increased interest and at least some fraction of the increased principal. We assume that \( g \) is constant, \( g_t = \bar{g} \). From market clearing we have

\[ c_t + g_t = y_t. \]
**A. Optimal Decisions for Private Sector**

As in (Evans, Guse, and Honkapohja 2008), the first-order conditions for an optimum yield

\begin{align}
0 &= -h_{t,s}^e + \frac{\alpha \gamma}{\nu} (\pi_{t,s} - 1)\pi_{t,s} \frac{1}{h_{t,s}} + \alpha \left( 1 - \frac{1}{\nu} \right) y_t^{1/\nu} y_{t,s}^{(1-1/\nu)} c_{t,s}^{-\sigma_1} \\
&\quad - \frac{\alpha \gamma \beta}{\nu} \frac{1}{h_{t,s}} E_{t,s}(\pi_{t+1,s} - 1)\pi_{t+1,s},
\end{align}

(6)

\begin{align}
c_{t,s}^{-\sigma_1} &= \beta R_t E_{t,s} \left( \pi_{t+1}^{-1} c_{t+1,s}^{-\sigma_1} \right),
\end{align}

(7)

\begin{align}
m_{t,s} &= (\chi \beta)^{1/\sigma_2} \left( \frac{(1 - R_t^{-1}) c_{t,s}^{-\sigma_1}}{\pi_{t+1}^{\sigma_2-1} E_{t,s}^{\sigma_2-1}} \right)^{-1/\sigma_2}.
\end{align}

(8)

Here \( \pi_{t+1,s} = P_{t+1,s}/P_{t,s} \). Equation (6) is the nonlinear New Keynesian Phillips curve describing optimal price-setting. The term \( (\pi_{t,s} - 1)\pi_{t,s} \) arises from the quadratic form of the adjustment costs, and this expression is increasing in \( \pi_{t,s} \) over the allowable range \( \pi_{t,s} \geq 1/2 \). Equation (7) is the standard Euler equation giving the intertemporal first-order condition for the consumption path. Equation (8) is the money demand function resulting from the presence of real balances in the utility function.

We now summarize the decision rules for inflation and consumption so that they depend on forecasts of key variables over the infinite horizon (IH). The IH learning approach is emphasized by (Preston 2005) and (Preston 2006), and is used in (Evans and Honkapohja 2010) and (Benhabib, Evans, and Honkapohja 2014) to study the properties of a liquidity trap.

**B. The Infinite-horizon Phillips Curve**

A forward-looking pricing function is obtained by iterating the optimality condition (6), using the production and demand functions and a transversality condition from optimal price setting. Assume that (i) agents have point expectations, (ii) know from past experience the market clearing condition and that all prices are equal, and (iii) all agents are identical with the utility of consumption and of money logarithmic \( (\sigma_1 = \sigma_2 = 1) \). Then
the pricing function takes the form (see the online appendix for details)

\[
Q_t = \frac{\nu}{\alpha \gamma} y_t^{(1+\varepsilon)/\alpha} - \frac{\nu - 1}{\gamma} y_t (y_t - \bar{g})^{-1} + \\
\frac{\nu}{\gamma} \sum_{j=1}^{\infty} \alpha^{-1} \beta^j (y_{t+j}^e)^{(1+\varepsilon)/\alpha} - \frac{\nu - 1}{\gamma} \sum_{j=1}^{\infty} \beta^j \left( \frac{y_{t+j}^e}{y_{t+j}^e - g} \right) \\
= \tilde{K}(y_t, y_{t+1}^e, y_{t+2}^e), \text{ where } Q_t = \pi_t (\pi_t - 1).
\]

The expectations in (9) are formed at time \( t \) and based on information at the end of period \( t - 1 \). Actual variables at time \( t \) are assumed to be in the information set of the agents when they make current decisions. We will treat (9) as the temporary equilibrium equations that determine \( \pi_t \), given expectations \( \{y_{t+j}^e\}_{j=1}^{\infty} \).

**C. The Consumption Function**

Derivation of the consumption function under given expectations is mostly standard, the details are in the online appendix. Using the Euler equation (7), money demand (8), the flow budget constraint and the intertemporal budget constraint in terms of expectations in any given period \( t \), we obtain the consumption function given in the appendix. To simplify the analysis, we assume that consumers are Ricardian. With this assumption the consumption function becomes

\[
c_t = (1 - \beta) \left( y_t - \bar{g} + \sum_{j=1}^{\infty} (D_{t,t+j}^c)^{-1} (y_{t+j}^e - g) \right), \text{ where }
\]

\[
D_{t,t+j}^c = \frac{R_t}{\pi_{t+1}^e} \prod_{i=2}^{j} \frac{R_{t+i-1}^e}{\pi_{t+i}^e} \text{ with } \pi_{t+i}^e = R_{t+i-1}^e / \pi_{t+i}^e.
\]

so that the household consumes the fraction \( 1 - \beta \) of the present value of current and expected net income, with the latter defined as gross output minus government spending on goods.
III. Temporary Equilibrium and Learning

To proceed further, formulation of learning needs to be discussed (see footnote 5 for general references on adaptive learning). In adaptive learning it is assumed that each agent has a model for perceived dynamics of state variables, also called the perceived law of motion (PLM), to make his forecasts of relevant variables. In any period the PLM parameters are estimated using available data and the estimated model is used for forecasting. The PLM parameters are re-estimated when new data becomes available.

A common formulation is to postulate that the PLM is a linear regression model where endogenous variables depend on intercepts, observed exogenous variables and possibly lags of endogenous variables. The estimation would then be based on least squares or related methods. The regression formulation cannot be applied here because there would be asymptotic perfect multicollinearity in the current non-stochastic setting.\textsuperscript{12} We therefore assume that agents form expectations using so-called steady state learning which is formulated as follows.

Steady-state learning with point expectations is formalized as

\[(11) \quad s_{t+j}^e = s_t^e \text{ for all } j \geq 1, \text{ and } s_t^e = s_{t-1}^e + \omega_t(s_t - s_{t-1})\]

for variables \(s = y, \pi, R\). It should be noted that expectations \(s_t^e\) refer to future periods (and not the current one). It is assumed that when forming \(s_t^e\) the newest available data point is \(s_{t-1}\), i.e. expectations are formed in the beginning of the current period and current-period values of endogenous variables are not yet known.

\(\omega_t\) is called the “gain sequence” and measures the extent of adjustment of the estimates to the most recent forecast error. In stochastic systems one often sets \(\omega_t = t^{-1}\) and this “decreasing gain” learning corresponds to least-squares updating. Also widely used is the case \(\omega_t = \omega\), for \(0 < \omega \leq 1\), called “constant gain” learning. In this case it is assumed that \(\omega\) is small.

The temporary equilibrium equations with steady-state learning are:
1. The aggregate demand

\begin{equation}
\begin{aligned}
y_t &= \bar{g} + (\beta^{-1} - 1)(y_t^e - \bar{g}) \left( \frac{\pi_t^e}{R_t} \right) \left( \frac{R_t^e}{R_t - \pi_t^e} \right) \\
&\equiv Y(y_t^e, \pi_t^e, R_t, R_t^e).
\end{aligned}
\end{equation}

Here it is assumed that agents do not know the interest rate rule of the monetary policy maker, so they need to forecast future interest rates. The forecasts are equal for all future periods, given that we are assuming steady-state learning.

2. The nonlinear Phillips curve

\begin{equation}
\begin{aligned}
\pi_t &= Q^{-1}[\tilde{K}(y_t, y_t^e, y_t^e \ldots)] \equiv Q^{-1}[K(y_t, y_t^e)] \equiv \Pi(y_t, y_t^e),
\end{aligned}
\end{equation}

where \( \tilde{K}(.) \) is defined in (9) and \( Q(\pi_t) \equiv (\pi_t - 1) \pi_t \).

\begin{equation}
\begin{aligned}
\tilde{K}(y_t, y_t^e) &= \frac{\nu}{\gamma} \left( \left( \alpha^{-1} y_t^{e(1+\varepsilon)/\alpha} - (1 - \nu^{-1}) \frac{y_t}{y_t - \bar{g}} \right) + \\
&\quad \frac{\nu}{\gamma} \left( \beta(1 - \beta)^{-1} \left( \alpha^{-1} y_t^{e(1+\varepsilon)/\alpha} - (1 - \nu^{-1}) \frac{y_t^e}{y_t^e - \bar{g}} \right) \right).
\end{aligned}
\end{equation}

\( Q \geq -\frac{1}{4} \) is imposed and the appropriate root for given \( Q \) is \( \pi \geq \frac{1}{2} \).

3. Interest rate rules are specified in the next section.

We remark that with Ricardian consumers the dynamics for bonds and money do not influence the determination of inflation, output and the interest rate in temporary equilibrium, though clearly the evolution of \( b_t \) and \( m_t \) is influenced by the sequence of these equilibria (see the appendix).

The system in general has three expectational variables: output \( y_t^e \), inflation \( \pi_t^e \), and the interest rate \( R_t^e \). We now assume that private agents formulate these expectations using steady state learning, so the dynamics are

\begin{equation}
\begin{aligned}
y_t^e &= y_t^{e-1} + \omega(y_{t-1} - y_t^{e-1}),
\end{aligned}
\end{equation}

\begin{equation}
\begin{aligned}
\pi_t^e &= \pi_t^{e-1} + \omega(\pi_{t-1} - \pi_t^{e-1}),
\end{aligned}
\end{equation}

\begin{equation}
\begin{aligned}
R_t^e &= R_t^{e-1} + \omega(R_{t-1} - R_t^{e-1}).
\end{aligned}
\end{equation}
IV. Monetary Policy Frameworks

Our aim is to compare the performance of price-level and nominal GDP targeting against each other and also against inflation targeting (IT). A basic assumption maintained throughout the paper is that agents do not know the interest rate rule or even its functional form. We think that this assumption is probably the realistic case. Section III. above, where agents form expectations about future interest rates and private agents learn according to (15)-(17) conforms to this assumption. The same setting is made also for price-level and nominal GDP targeting regimes but with forward guidance the policy maker also makes a credible announcement of the target path for the price level or nominal GDP, respectively. The interest rate rule remains unknown even in the presence of forward guidance from the target path.

For concreteness and simplicity of the comparisons we model IT in terms of the standard Taylor rule

\[ R_t = 1 + \max[\bar{R} - 1 + \psi_\pi(\pi_t - \pi^*) + \psi_y[(y_t - y^*)/y^*], 0], \]

where \( \bar{R} = \beta^{-1}\pi^* \) is the gross interest rate at the target and we have introduced the ZLB, so that the gross interest rate cannot fall below one. For analytical ease, we adopt a piecewise linear formulation of the interest rate rule. The inflation target \( \pi^* \) for the medium to long run is assumed to be known to private agents but as indicated, agents do not known the rule (18). We also remark that it would be possible to introduce an effective interest rate lower bound greater than one. Neither the theoretical results nor the qualitative aspects of numerical results would be affected.

A. Price-level Targeting

We begin by noting that a number of formulations for price-level targeting (PLT) exist in the literature. We consider a simple formulation, where (i) the policy maker announces an exogenous target path for the price level as a medium to long run target and (ii) sets the policy instrument with the intention to move the actual price level gradually toward a targeted price
level path. These kinds of instrument rules are called Wicksellian, see pp. 260-61 of (Woodford 2003) and (Giannoni 2012) for discussions of Wick- sellian rules. In particular, (Giannoni 2012) analyses a number of different versions of the Wicksellian rules.\textsuperscript{13}

We assume that the target price level path \( \{ \bar{P}_t \} \) involves constant inflation, so that

\begin{equation}
\bar{P}_t / \bar{P}_{t-1} = \pi^* \geq 1. 
\end{equation}

The interest rate, which is the policy instrument, is set above (below, respectively) the targeted steady-state value of the instrument when the actual price level is above (below, respectively) the targeted price-level path \( \bar{P}_t \), as measured in percentage deviations. The interest rate is also allowed to respond to the percentage gap between targeted and actual levels of output. The target level of output \( y^* \) is the steady state value associated with \( \pi^* \). This leads to a \textbf{Wicksellian interest rate rule}

\begin{equation}
R_t = 1 + \max[ \bar{R} - 1 + \psi_p((P_t - \bar{P}_t)/\bar{P}_t) + \psi_p((y_t - y^*)/y^*], 0],
\end{equation}

where the \textit{max} operation takes account of the ZLB on the interest rate. To have comparability to the IT rule (18), we adopt a piecewise linear formulation of the interest rate rule.

The target price level path becomes known to the private agents once a move to the PLT policy regime is made. Given the ZLB for the interest rate, the price and output gap terms \( (P_t - \bar{P}_t)/\bar{P}_t \) and \( (y_t - y^*)/y^* \) act as triggers that lead to the lifting of the interest rate from its lower bound if either actual price level or output meets its target value.

As already mentioned, regarding interest rate setting it is assumed that the form of the interest rate (20) is not made known to private agents. For expectations formation there are two possible assumptions. One possibility is that agents forecast future inflation in the same way as under IT, so that inflation expectations adjust in accordance with (16). A second possibility is that private agents make use of the announced target price level path in the inflation forecasting. It turns out that ignorance vs. use of this forward
guidance is a key issue for the properties of PLT regime.

B. Nominal GDP Targeting

To have comparability to PLT, we model nominal GDP targeting in terms of an instrument rule similar to Wicksellian PLT rule, e.g., see (Clark 1994) and (Judd and Motley 1993). The monetary authority then sets the interest rate above (below) the targeted steady-state value $\bar{R}$ if actual nominal GDP $P_y$ is above (respectively, below) the targeted nominal GDP path $\{\bar{z}_t\}$. In line with a standard NK model, we assume that there is an associated inflation objective $\pi^* \geq 1$ calling for a non-negative (net) inflation rate and that the economy does not have any sources for trend real growth. Then the nominal GDP target is formally $\bar{z}_t = P_y^*$ with $P_t/P_{t-1} = \pi^*$. Taking the ratio, the path of nominal GDP growth satisfies $\bar{z}_t/\bar{z}_{t-1} = \Delta \bar{z} = \pi^*$. Taking into account the ZLB, such an interest rate rule takes the form

\begin{equation}
R_t = 1 + \max[\bar{R} - 1 + \psi((P_t - \bar{z}_t)/\bar{z}_t), 0],
\end{equation}

where $\psi > 0$ is a policy parameter. Below we refer to (21) as the NGDP interest rate rule. This policy regime follows the general setting that is specified above for the PLT policy regime. The target path for nominal GDP is announced as a medium to long target, but the interest rate rule (21) remains unknown to the private agents. The agents may discard or use knowledge of the target path in their inflation forecasting.

We remark that these forms of PLT and NGDP targeting follow the spirit of the suggestion of (Woodford 2012), pp. 228-30, that a target value for nominal GDP is used to act as a trigger for increasing the interest rate above its lower bound.
V. Expectation Dynamics

A. Steady States

A non-stochastic steady state \((y, \pi, R)\) under PLT must satisfy the Fisher equation \(R = \beta^{-1}\pi\), the interest rate rule (20), and steady-state form of the equations for output and inflation (12) and (13). One steady state clearly obtains when the actual inflation rate equals the inflation rate of the price-level target path, see equation (19). Then \(R = \bar{R}, \pi = \pi^*\) and \(y = y^*\), where \(y^*\) is the unique solution to the equation

\[ \pi^* = \Pi(Y(y^*, \pi^*, \bar{R}, \bar{R}, y^*)]. \]

Moreover, for this steady state \(P_t = \bar{P}_t\) for all \(t\).

Then consider steady states under NGDP targeting. One steady state obtains when the economy follows the targeted nominal GDP path, so that \(R = \bar{R}, \pi = \pi^*\) and \(y = y^*\) and \(\pi^* = \Delta \bar{\varepsilon}\).

The targeted steady state under either PLT or NGDP rule is, however, not unique. Intuitively, the Fisher equation \(R = \beta^{-1}\pi\) is a key equation for a nonstochastic steady state and \(\bar{R}, \pi^*\) satisfies the equation. If policy sets \(R = 1\), then \(\hat{\pi} = \beta < 1\) becomes a second steady state as the Fisher equation also holds at that point. Formally, there is a second steady state in which the ZLB condition is binding:

**Proposition 1.** (a) Assume that \(\beta^{-1}\pi^* - 1 < \psi_p\). Under the Wicksellian PLT rule (20), there exists a ZLB-constrained steady state in which \(\hat{R} = 1, \hat{\pi} = \beta, \) and \(\hat{y}\) solves the equation

\( \hat{\pi} = \Pi(Y(\hat{y}, \hat{\pi}, 1, 1), \hat{y}). \)

(b) Assume that \(\beta^{-1}\pi^* - 1 < \psi\). The ZLB-constrained steady state \(\hat{R}, \hat{\pi}, \) and \(\hat{y}\) exists under the NGDP interest rate rule (21). In the ZLB-constrained steady state the price level \(P_t\) converges toward zero, so that the price-level target \(\bar{P}_t\) or NGDP target \(\Delta \bar{\varepsilon}\), respectively, is not met.

We remark that the sufficient condition \(\beta^{-1}\pi^* - 1 < \psi_p\) or \(\beta^{-1}\pi^* - 1 < \psi\)
is not restrictive as for a quarterly calibration below with $\beta = 0.99$ and $\pi^* = 1.005$ one has $\beta^{-1}\pi^* - 1 = -0.00505$. The lemma states that, like IT with a Taylor rule, commonly used formulations of price-level and NGDP targeting both suffer from global indeterminacy as the economy has two steady states under either monetary policy regime.

**B. Dynamics, Basic Considerations**

We now begin to consider dynamics of the economy in these regimes under the hypothesis that agents form expectations of the future using adaptive learning. Expectations of output, inflation and the interest rate influence their behavior as is evident from equations (12) and (13). Our formal approach is initially illustrated by considering the inflation targeting regime under opacity when the policy rule and its functional form are unknown but agents know the inflation target $\pi^*$. Then agents’ expectations are given by equations (15)-(17) under steady-state learning.

We remark that in the IT regime, knowledge of the target inflation rate $\pi^*$ does not add to forward guidance to expectations as $\pi^*$ is a constant. Forecasting the gap between $\pi$ and $\pi^*$ is equivalent to forecasting future $\pi$.

Under IT the temporary equilibrium system is (12), (13), and (18) in an abstract form

$$F(x_t, x_t^e, x_{t-1}) = 0,$$

where the vector $x_t$ contains the dynamic variables. The vector of state variables is $x_t = (y_t, \pi_t, R_t)^T$. The learning rules (15)-(17) can be written in vector form as

$$x_t^e = (1 - \omega)x_{t-1}^e + \omega x_{t-1}.$$

This system is both high-dimensional and nonlinear and we first consider local stability properties of steady states under the rule (18) using linearization (see the Appendix for details).

**Definition.** The steady state is said to be **expectationally stable** or
(locally) stable under learning if it is a locally stable fixed point of the system (D1) and (24) for all $0 \leq \omega < \bar{\omega}$ for some $\bar{\omega} > 0$.

Conditions for this can be directly obtained by analyzing (23)-(24) in a standard way as a system of difference equations. Alternatively, so-called expectational (E-stability) techniques can be applied, see for example (Evans and Honkapohja 2001). Both methods are used in the Appendix in the proofs of the Propositions.

We remark that the local stability conditions under learning for the IT regime (18) are given by the well-known Taylor principle for various versions of the model and formulations of learning. The seminal paper is (Bullard and Mitra 2002) and a recent summary is given e.g. in (Evans and Honkapohja 2009a) and in Section 2.5 of (Evans and Honkapohja 2013). In our setup theoretical results can be obtained when price adjustment costs are not too large. For completeness, here is the formal stability result in our setup for IT with opacity (the proof is in the online appendix):

**Proposition 2.** In the limit $\gamma \rightarrow 0$ the targeted steady state is expectationally stable if $\psi_{\pi} > \beta^{-1}$ under IT.

By continuity of eigenvalues the result implies a corresponding condition for $\gamma$ sufficiently small. In the text we carry out numerical simulations for other parameter configurations in the different policy regimes. The learning dynamics converge locally to the targeted steady state for $\pi$ and $y$ for many cases with non-zero value of $\gamma$.

However, for the low steady state we have instability:

**Proposition 3.** The ZLB-constrained steady state is not expectationally stable under IT.

We remark that under the ZLB constraint the dynamics for IT, PLT and NGDP policy regimes are identical as is evident from the interest rate rules in Section IV. Formally, the dynamics are given by

\[
\Delta y_t^c = \omega(Y(y_{t-1}^c, \pi_{t-1}^c, 1, 1) - y_{t-1}^c)
\]
\[
\Delta \pi_t^c = \omega(\Pi(Y(y_{t-1}^c, \pi_{t-1}^c, 1, 1), y_{t-1}^c) - \pi_{t-1}^c).
\]
The learning dynamics under the ZLB-constraint (and assuming \( R_t = R_t^e = 1 \)) are illustrated in Figure 1 using the calibration below.\(^{16}\)

![Figure 1: Dynamics of inflation and output expectations in the constrained region without forward guidance.](image)

In Figure 1 the vertical isocline comes from the equation \( \Delta y_t^e = 0 \) and the downward-sloping curve is from equation \( \Delta \pi_t^e = 0 \). It is seen that in the ZLB region, which is south-west part of the state space bound by the isoclines \( \Delta \pi_t^e = 0 \) and \( \Delta y_t^e = 0 \) (shown by the two curves), the dynamics imply a deflation trap, i.e. expectations of inflation and output slowly decline under unchanged policies.

In the general analysis for PLT and NGDP targeting the vector of state variables needs to augmented in view of the interest rate rule. For example, under PLT one introduces the variable \( X_t = P_t / \bar{P}_t \), so that it is possible to analyze also the situation where the actual price level is explosive. We then have a further equation \( X_t = \pi_t X_{t-1} / \pi^* \) and the state variables are \( x_t = (y_t, \pi_t, R_t, X_t)^T \).

### VI. Forward Guidance from Price-Level or Nominal GDP Targeting

A key observation is that PLT and NGDP targeting regimes include a further piece of dynamic information, namely the target path for the price
level or nominal GDP, respectively. If PLT (or NGDP targeting) is fully credible, then agents naturally incorporate this piece of information in their forecasting. We now describe a simple formulation of how to use data about the gap between actual and target paths in inflation forecasting.\(^{17}\)

### A. PLT with Forward Guidance

We start with the PLT regime and assume that agents incorporate the target price level path in their learning. It is assumed that agents forecast the future values of gap between the actual and targeted price levels and then infer the associated expectations of inflation from the forecasted gap. The gap is measured as the ratio \( X_t \equiv P_t / \bar{P}_t \) and so

\[
X_t \equiv X_{t-1} \times \left( \frac{\pi_t}{\pi^*} \right). 
\]

Moving (25) one period forward, agents can compute the inflation forecast from the equation

\[
t X_t^e \pi_t^e = (X_t^e \times \pi^*),
\]

assuming as before that information on current values of endogenous variables is not available at the time of forecasting. \( X_t^e \) denotes the forecasted value of the gap for the future periods and \( t X_t^e \) refers to the forecast of the current gap \( X_t \) in the beginning of period \( t \).\(^{18}\) The inflation forecasts \( \pi_t^e \) from (26) are substituted into the aggregate demand function (12).

It remains to specify how the expectations \( X_t^e \) and \( t X_t^e \) are formed. Agents are assumed to update \( X_t^e \) by using steady-state learning:

\[
X_t^e = X_{t-1}^e + \omega(X_{t-1} - X_{t-1}^e).
\]

It is also assumed that \( t X_t^e \) is a weighted average of the most recent observation \( X_{t-1} \) and the previous forecast \( X_{t-1}^e \) of the gap for period \( t \). Formally,

\[
t X_t^e = \omega_1 X_{t-1} + (1 - \omega_1) X_{t-1}^e,
\]
where $\omega_1$ is a positive weight.

Output and interest rate expectations are assumed to be done as before, see equations (15) and (17). The temporary equilibrium is then given by equations (26), (12), (13), (20) and the actual relative price is given by (25). We remark that Proposition 1 continues to hold when agents use forward guidance under PLT (or NGDP) regime. As regards local stability properties of the steady states, in the case $\gamma \to 0$ of small adjustment costs we have a theoretical result:

Proposition 4. Consider the PLT regime with forward guidance and assume that agents forecast as specified by equations (26)-(27) and that $\pi^* \geq 1$ and $\gamma \to 0$. The targeted steady state $\pi = \pi^*$ and $R = \beta^{-1}\pi^*$ is expectationally stable when $0 < \psi_p < \beta^{-1}$.

The proof is in the online appendix. Below we numerically examine local instability of the low steady state and it seems to be totally unstable.

B. NGDP Targeting with Forward Guidance

The case of NGDP targeting with forward guidance can be formulated as follows. Agents are assumed to forecast future inflation by making use of the gap between actual and targeted level of nominal GDP. We measure the gap as the ratio $P_t y_t / \bar{z}_t \equiv Y_t$. Then use the identity

\begin{equation}
\pi_t y_t / y_{t-1} \equiv Y_t \bar{z}_t / Y_{t-1} \bar{z}_{t-1} \text{ or } Y_{t-1} y_t \pi_t \equiv \Delta \bar{z}_t Y_t y_{t-1},
\end{equation}

where $\bar{z}_{t+1} / \bar{z}_t = \Delta \bar{z}$. Given forecasts $Y^e_t$, $y^e_t$, $Y^e_t$ and $y^e_t$, agents compute the inflation forecast $\pi^e_t$ from

\begin{equation}
t Y^e_t y^e_t \pi^e_t = \Delta \bar{z}_t Y^e_t.
\end{equation}

Here $t y^e_t$ and $t Y^e_t$ refer to forecasts of current-period values of $y_t$ and $Y_t$, respectively, made at the beginning of period $t$. They are computed as weighted average of the previous forecast for period $t$ and the latest data points of each variable. We are making the same assumption about available information at the moment of forecasting as in (26). Agents are assumed
to use steady-state learning for the gap forecast

\[(31) \quad Y_t^e = Y_{t-1}^e + \omega(Y_{t-1} - Y_{t-1}^e)\]

and the forecasts \(iy_t^e\) and \(iY_t^e\) are made as

\[(32) \quad iy_t^e = \omega_1 y_{t-1} + (1 - \omega_1)y_{t-1}^e,\]
\[(33) \quad iY_t^e = \omega_1 Y_{t-1} + (1 - \omega_1)Y_{t-1}^e,\]

which are analogous to equation (28). Agents forecast output and the interest rate using the earlier learning rules (15) and (17). From (29) the actual value of the nominal GDP gap in temporary equilibrium is recursively

\[Y_t = (\Delta \bar{z})^{-1}\pi_t(y_t/y_{t-1})Y_{t-1}.\]

In the targeted steady state the limit is \(Y_t = 1\). For the ZLB-constrained steady state it is seen that in the limit \(Y_t \rightarrow 0\). A theoretical result for local stability of the steady states is available when \(\gamma \rightarrow 0\). The following proposition is proved in the online appendix:

**Proposition 5.** Consider NGDP regime with forward guidance and assume that agents’ forecasting is specified by equations (30)-(33) and that \(\pi^* \geq 1\) and \(\gamma \rightarrow 0\). The targeted steady state \(\pi = \pi^*\) and \(\hat{R} = \beta^{-1}\pi^*\) is expectationally stable when \(\psi > \pi^*(1 - \beta)/\beta\).

We remark that the condition \(\psi > \pi^*(1 - \beta)/\beta\) is very seldom binding as \(\beta\) is very close to one. For example, with \(\pi^* = 1.005\) and \(\beta = 0.99\), the condition holds if \(\psi > 0.0102\).

**C. Robust Stability Under PLT and NGDP Rules with Forward Guidance**

We now take a global viewpoint to requiring convergence to the targeted steady state under a policy regime by computing the domain of attraction for the targeted steady state under PLT or NGDP targeting with forward guidance. As discussed in the Introduction, the size of the domain
of attraction is taken as a robustness criterion for a policy regime. A larger domain of attraction means that the regime can deliver convergence to the target after bigger shocks. Thus, a regime is better than some other regime if the targeted steady state has a larger domain of attraction.

The assumption that private agents incorporate in their learning the forward guidance from either the price-level or nominal GDP target is now used to analyze of the domain of attraction of the targeted steady state under PLT and NGDP rules, respectively. Our discussion focuses on the PLT case. Output and interest rate expectations follow (15) and (17), while the temporary equilibrium is given by equations (12), (13), (20) and (25).

For simplicity, the simulations assume through the rest of the paper that $1 = 1$ in (26), so that the price gap expectations follow (27) and inflation expectations are given by $\pi_t^e = (X_t^e \times \pi^e)/X_{t-1}$.

We focus on sensitivity with respect to displacements of initial output and relative price level expectations $y_0^e$ and $X_0^e$ by computing partial domain of attraction for the targeted steady state. The analysis is necessarily numerical, so values for structural and policy parameters must be specified.

The calibration for a quarterly framework $\pi^* = 1.005$, $\beta = 0.99$, $\alpha = 0.7$, $\gamma = 128.21$, $\nu = 21$, $\varepsilon = 1$, and $g = 0.2$ is used. The values of $\beta$, $\alpha$, and $g$ are standard. The chosen value of $\pi^*$ corresponds to two percent annual inflation rate. We set the labor supply elasticity $\varepsilon = 1$. The value for $\gamma$ is based on a 15% markup of prices over marginal cost suggested in (Leeper, Traum, and Walker 2011) (see their Table 2) and the price adjustment costs are estimated from the average frequency of price reoptimization at intervals of 15 months (see Table 1 in (Keen and Wang 2007)). It is also assumed that interest rate expectations $r^e_{t+j} = R_{t+j-1}/\pi^e_{t+j}$ revert to the steady state value $\beta^{-1}$ for $j \geq T$.

We use $T = 28$. To facilitate the numerical analysis the lower bound on the interest rate $R$ is sometimes set slightly above 1 at value 1.0001. The gain parameter is set at $\omega = 0.002$, which is a low value. Sensitivity of this choice is discussed below.

The targeted steady state is $y^* = 0.943254$, $\pi^* = 1.005$ and the low steady state is $y_L = 0.943026$, $\pi_L = 0.99$. For policy parameters in the PLT regime we adopt the values $\psi_p = 0.25$ and $\psi_y = 1$, which are also 20.
used by (Williams 2010). For NGDP targeting with the rule (21) the policy parameter is specified as $\psi = 0.8$.\textsuperscript{22}

The system is high-dimensional, so only partial domains of attraction can be obtained in the two-dimensional space. In the computation, the set of possible initial conditions for $X_0^c$ and $y_0^c$ is made quite large and we set the initial values of the other variables at the deflationary steady state $\bar{R} = 1$, $\bar{\pi} = \beta$, and $y = \bar{y}$, except that the gap variables $X_0$ and $X_0^c$ were set at values slightly above 0. Also set $R_0 = R_0^c = 1$ and $X_0 = X_0^c$. The grid search for $y_0^c$ was over the range 0.94 to 1 at intervals of 0.0005 and that for $X_0^c$ over the range 0.1 to 2 at intervals of 0.02 with the baseline gain. (Recall that for equation (28) it is assumed that $\omega_1 = 1$ for simplicity.\textsuperscript{23})

Dramatically, convergence to the target steady state is very robust:

**Result:** The domain of attraction is very large under the PLT (and NGDP) rules with forward guidance and contains even values for $y_0^c$ well below the low steady state.

Figure A.1 in the appendix shows the partial domain of attraction for the PLT policy rule with the specified initial conditions and very wide grids for $y_0^c$ and $X_0^c$. Other simulations have been run for a shock to $R_0^c$ with analogous results (details are not reported for reasons of space). We remark that the corresponding result for NGDP targeting turns out to be the same, so we do not report the corresponding figure.\textsuperscript{24} The domain of attraction for PLT with forward guidance is much larger than under IT; see Figure 3 below for the latter.

We emphasize that the preceding set of initial conditions includes cases of large pessimistic shocks that have taken the economy to a situation where the ZLB is binding. Forward guidance from the PLT path in agents’ forecasting plays a key role in moving the economy out of the liquidity trap toward the targeted steady state. The mechanism works through deviations of the price level from the target path, i.e., the gap variable $X_t$ influencing inflation expectations. It can be understood as follows.

First, note that identity (25) implies that $X_t/X_{t-1} = \pi_t/\pi^*$, so that the price gap variable $X_t$ decreases whenever inflation is below the target value. In the region where ZLB is binding (and $R_0 = R_0^c = 1$ imposed)
the dynamics of gap expectations $X_t^e$ translate into dynamics of inflation expectations taking the form

\begin{equation}
\pi_t^e = \pi_{t-1}^e (\pi^*/\Pi(y_{t-1}^c, \pi_{t-1}^e))(1 - \omega) + \omega \pi^*,
\end{equation}

where $\pi_{t-1} = \Pi(y_{t-1}^c, \pi_{t-1}^e) = \Pi(Y(y_{t-1}^c, \pi_{t-1}^e, 1, 1, y_{t-1}^c)$ by (13). Equation (34) results from combining equations (27) and (26) and assuming that $\omega_1 = 1$. The equation indicates that as the price gap $\pi^*/\Pi(y_{t-1}^c, \pi_{t-1}^e) = \pi^*/\pi_{t-1}^e$ widens (i.e. $X_t$ declines) in the constrained region, the gap term raises inflation expectations, *ceteris paribus*.

We illustrate the dynamics for $\pi_t^e$ and $y_t^c$ resulting from equations (34) and (15) with $R_t = R_t^e = 1$ in Figure 2.

![Figure 2: Dynamics of inflation and output expectations in the constrained region with forward guidance.](image)

The vertical line is again obtained from equation $\Delta y_t^c = 0$ and the downward-sloping curve from equation $\Delta \pi_t^e = 0$. Figure 2 shows that forward guidance from PLT path leads to increasing inflation expectations in the South-West (constrained) region bound by the two isoclines. (Derivation of (34) assumes that $X_t$ and $X_t^e$ are not zero, so that the intersection of the isoclines in Figure 2 is undefined.) This adjustment eventually takes the economy out of the constrained region and there is convergence toward the targeted steady state.
This effect is absent from the dynamics for $\pi_t^e$ when there is no forward guidance, as inflation expectations then evolve according to (16). Recall that Figure 1 shows the deflation trap dynamics of $\pi_t^e$ and $y_t^e$ in the constrained region when agents do not incorporate the target price level path into their expectations formation, i.e. forward guidance is not effective. The contrast is evident by comparing Figures 1 and 2.

If agents have incorporated forward guidance from PLT into their expectations formation, the price level target path continues to influence the economy through inflation expectations even when ZLB is binding. This analysis lends new support to the suggestion of (Evans 2012) that guidance from price-level targeting can be helpful in a liquidity trap. Monetary policy alone is able to pull the economy out of the liquidity trap if PLT or NGDP can be implemented so that agents include the provided forward guidance into their expectations formation.25

VII. The Case of No Forward Guidance

It is clearly possible that agents do not include the forward guidance in their forecasting. This could happen simply because after a shift from IT to PLT or NGDP agents stick with their earlier forecasting practice. Alternatively, agents may not regard the new policy regime fully credible and use forecasting methods that only employ actual data.

A. Stability Results

We start with local stability results. The system under PLT without forward guidance consists of equations (12), (13), (20) and (25), together with the adjustment of output, inflation and interest rate expectations given by (15), (16) and (17) and under NGDP targeting the system is the same except that the interest rate rule is (21) in place of (20). As before, theoretical derivation of learning stability conditions for the PLT and NGDP targeting regimes is in general intractable, but results are available in the limiting case $\gamma \to 0$ of small price adjustment costs.26 The online appendix contain proofs for the following results:
Proposition 6. Assume $\gamma \to 0$ and that agents’ inflation forecast is given by (16). If $\psi_p > 0$ under the PLT rule (20), the targeted steady state $\pi = \pi^* \geq 1$ and $R = \beta^{-1}\pi^*$ is expectationally stable.

Proposition 7. Assume $\gamma \to 0$ and that agents’ inflation forecast is given by (16). Then the targeted steady state with $\pi^* \geq 1$ and $R = \beta^{-1}\pi^*$ is expectationally stable under the NGDP rule (21) when $\psi > 0$.

B. Domains of Attraction

IT, PLT and NGDP targeting without forward guidance are now compared in terms of the domains of attraction of the target steady state. Results for the domains of attraction for the three rules are in Figure 3.

![Figure 3: Domains of attraction for IT (left panel), NGDP (middle panel) and PLT (right panel). Horizontal axis gives $y_0^c$ and vertical axis $\pi_0^c$. Shaded area indicates convergence. The circle in the shaded region is the intended steady state and the other circle is the unintended steady state.](image)

In Figure 3 the calibration and most numerical assumptions are as before. For the IT rule (18) the policy parameter values are set at the usual values $\psi_\pi = 1.5$ and $\psi_y = 0.5/4$. We focus on sensitivity with respect to initial inflation and output expectations $\pi_0^c$ and $y_0^c$. Initial conditions on the interest rate $R_0$ and its expectations $R_0^e$ are set at the target value, while initial conditions on actual inflation and output are set at $y_0 = y_0^c + 0.0001$ and $\pi_0 = \pi_0^c + 0.0001$. Also $X_0 = 1.003$ under PLT. We simulate the model for various values of initial inflation and output expectations, $\pi_0^c$ and $y_0^c$. $\pi_0^c$
ranges from 0.935 to 1.065 at steps of 0.002 while $y_0^*$ varies from 0.923254 and 0.963254 at steps of 0.0005. We say convergence has been attained when both $\pi_t$ and $y_t$ are within 0.5% of the targeted steady state; otherwise we say the dynamics does not converge.\textsuperscript{27}

It is seen that PLT and NGDP regimes are clearly much less robustly convergent than IT. The NGDP rule is slightly more robust than PLT rule.

**VIII. Further Aspects of Learning Dynamics**

**A. Adjustment under PLT and Nominal GDP Targeting:**

**Dynamic Paths and Volatility**

The focus is now shifted to the adjustment of the economy under learning in the three monetary policy regimes (IT, PLT and NGDP targeting) after a small shock has displaced the economy from the locally targeted steady state. Degree of volatility of adjustment is a further robustness property for policy regimes: how big are the fluctuations during the learning adjustment path? We note that forward guidance has a clear impact on the nature of dynamic adjustment, so PLT and NGDP targeting are analyzed with and without forward guidance.

The analysis has two parts. First, transitional adjustment dynamics of major variables after the displacement of initial conditions of the variables from the targeted steady state are considered.\textsuperscript{28} Second, we calculate a number of volatility measures for the dynamic adjustment paths. This latter exercise is similar to the sizeable literature that makes comparisons of IT and PLT with respect to measures of volatility, see (Svensson 1999) and the references therein.\textsuperscript{29}

The calibration specified in Section VI, C, is used in the simulations. We simulate the model for various values of initial inflation and output expectations, $\pi_0^*$ and $y_0^*$, in the neighborhood of the desired steady state. $\pi_0^*$ ranges in an interval of 1% around $\pi^*$ i.e. from 1.0025 to 1.0075 at steps of 0.0002 while $y_0^*$ varies in an interval around $y^*$; specifically between 0.94303 and 0.94355 at steps of 0.00001. The gain parameter is at a baseline value of 0.002. For initial output and inflation we set $y_0 = y_0^* + 0.001$ and

25
\[ \pi_0 = \pi_0^c + 0.001, \text{ and } \bar{R}_0 = \bar{R}.30 \] In PLT the initial deviation for the target path is set at \( X_0 = 1.003 \) i.e. 0.3% off. We operationalize the ZLB of the interest rate by setting the lower bound to be 1.0001.

The different volatility measures for inflation, output and interest rate during the learning adjustment are unconditional variances of the variables, a quadratic loss function in terms of the unconditional variances with the weights 0.5 for output, 0.1 for the interest rate and 1 for the inflation rate (following (Williams 2010)) and also the median ex post utility of the representative consumer. The explicit form of the utility is in Appendix E.

B. The Case without Forward Guidance

We begin by considering the basic features of the adjustment paths under adaptive learning. Under PLT the temporary equilibrium system is given by (12), (13), (20), and (25). Substituting (20) and (25) into the aggregate demand and Phillips curves (12) and (13), we obtain a system of two simultaneous nonlinear equations to solve for \( \pi_t \) and \( y_t \) given agents’ forecasts \( \pi_t^e, y_t^e \) and \( R_t^e \) formed at the beginning of \( t \) (based on data up to \( t - 1 \)). Given \( \pi_t \), then (25) determines \( X_t \) which along with \( y_t \) yields \( R_t.31 \)

It turns out that convergence for IT is monotonic after the initial jump, whereas for PLT and NGDP there is oscillatory convergence to the targeted steady state. The oscillations die away faster under NGDP than under PLT. Figure A.2 in the appendix illustrates the dynamics of inflation, output and the interest rate for IT, PLT and NGDP targeting when agents’ expectations do not include forward guidance. The appendix also provides some intuition for the qualitative paths of the variables even though simultaneity and nonlinearity of the underlying dynamics of the endogenous variables makes it difficult to provide precise intuition for the dynamic paths.

Table 1: Volatility of inflation, output and interest rate for different policy rules without forward guidance.

26
Note: the numbers should be multiplied by $10^{-6}$ (except for utility).

Table 1 reports the results for the chosen volatility measures when there is no forward guidance. The results are the median volatilities based on a run of 500 periods using our baseline gain of 0.002 for each policy. It is seen that in terms of output fluctuations, IT does clearly best, but it does much worse in terms of inflation and interest rate fluctuations. Overall, PLT and NGDP targeting perform similarly and the results for them are close to each other but they are very different from those for IT. Given the weights in the loss function, the PLT rule is slightly better overall than NGDP but ex post utility comparison turns the result mildly the other way. These two rules are clearly better than IT in terms of the quadratic loss function and ex post utility.

C. The Case with Forward Guidance

Our focus is the same as in Section B, but the comparison is between IT, PLT and NGDP targeting when agents’ expectations incorporate the forward guidance provided in the latter two regimes. First, we briefly consider the nature of learning adjustment paths emerge when a (small) shock has displaced the economy from the targeted steady state. Second, the different volatility measures are reported for the case with forward guidance.

It turns out that the dynamics in PLT and NGDP regimes to the targeted steady state are significantly altered when agents include forward guidance in their learning; compare Figures A.2 and A.4 in the appendix. The oscillations under PLT and NGDP die out much faster when forward guidance is used by private agents. This happens, for example, under PLT because inflation expectations and inflation are directly influenced by the lagged value $X_{t-1}$, see (25)-(26), which induces relatively fast adjustments also in output expectations and output and results in rapid convergence in the stable case. Without forward guidance inflation (respectively, output) expectations depend only on past inflation (respectively, output) and the movement is far more gradual with the oscillations in the variables dying out slowly. In terms of the magnitude of oscillations the results are mixed.
for forward guidance: inflation oscillations are smaller whereas they are slightly larger for output and the interest rate than when there is no forward guidance. Convergence of the endogenous variables under the PLT and NGDP regimes is quite rapid and mostly within 20 periods. In contrast convergence of all the variables is slower under IT.

Next, we calculate the same volatility measures for PLT and NGDP regimes when agents incorporate forward guidance in PLT and NGDP regimes into their learning. The details for the grid searches are largely the same as those in Table 1. However, with PLT the grid for relative price expectations $X_0^0$ is $[0.9975, 1.0025]$ and the initial relative price is set at $X_0 = X_0^0 + 0.0001$ (the grid for $y_0^0$ is the same as in Table 1). For NGDP the grid for relative output expectations $Y_0^0$ is the same as for $X_0^0$ and the initial relative output is set at $Y_0 = Y_0^0 + 0.0001$. The reported results are the median volatilities based on a run of 500 periods using our baseline gain of 0.002 for NGDP targeting and PLT. The final row reproduces the earlier results for IT from Table 1 to facilitate comparisons.

Table 2: Volatility of inflation, output and interest rate for NGDP and PLT with forward guidance.

Note: the numbers should be multiplied by $10^{-6}$ (except for utility).

Table 2 shows that forward guidance has clear benefits for NGDP and PLT. Volatilities in $\pi$ and $R$ are lower with forward guidance than without it though output volatility is slightly higher. Thus, PLT and NGDP perform much better than IT. In terms of utility and loss, PLT performs slightly better than NGDP. Volatility of inflation and output is lower and for interest rate higher under PLT than under NGDP. Note that inflation and interest rate volatilities under IT are much higher than both PLT and NGDP. This is reflective of the initial wide fluctuations in these variables under IT.

In the online appendix we make a comparison of the three regimes in terms of ranges of fluctuation for inflation, output and the interest rate and
in terms of the probability of hitting the zero lower bound during the adjustment. Forward guidance mostly improves the results about fluctuation ranges for both PLT and NGDP regimes and the likelihood of deflation also falls under PLT and NGDP. The ZLB is hit with positive probability in all regimes with the minimum occurrence under IT. The NGDP regime with forward guidance also fares well in this dimension.

Overall, the results lend support to the idea that PLT or NGDP targeting may well be better than IT in terms of volatilities in the dynamics. The big difference to the literature about such advantages represented e.g. by (Svensson 1999), (Vestin 2006) and (Jensen 2002) is that we have focused on dynamics of learning adjustment. We have also employed standard policy regimes rather than policies that are optimal under RE.

IX. Conclusion

Our study provides a new kind of assessment of price-level and nominal GDP targeting that have been recently suggested as possible improvements over inflation targeting policy. The results indicate that overall the performance of either price-level or nominal GDP targeting is clearly better than performance of inflation targeting, provided that private agents’ learning has incorporated the forward guidance from the price level or nominal GDP target path that these regimes entail. In particular, the domain of attraction of the target steady state under price-level and nominal GDP targeting is very large with basically global convergence (except from the deflationary steady state). If instead private agents’ learning does not use the forward guidance, the results are not clear-cut; IT has a clearly bigger domain of attraction than PLT or NGDP targeting but is worse in terms of volatility during the adjustment back to the target equilibrium. Thus, if a move to either price-level or nominal GDP targeting is contemplated, it is important to try to influence the way private agents form inflation expectations, so that the forward guidance is incorporated into their learning.

Our analysis has two important starting points. It is assumed that agents have imperfect knowledge and therefore their expectations are not rational during a transition after a shock. Agents make their forecasts using
an econometric model that is updated over time. In addition, we have carefully introduced the nonlinear global aspects of a standard framework, so that the implications of the interest rate lower bound can be studied. As is well-known, inflation targeting with a Taylor rule suffers from global indeterminacy and it was shown here that the same problem exists for standard versions of price-level and NGDP targeting.

The current results are a first step in this kind of analysis. Several extensions can be considered. We have used standard policy rules and standard values for the policy parameters, but these do not represent optimal policies. Deriving globally optimal rules in a nonlinear setting like ours is clearly extremely demanding, but one could consider optimal simple rules, i.e., optimization of the parameter values of these instrument rules. One could also do away with the instrument rule formulations used in this paper and instead postulate that the central bank employs a target rule whereby in each period the policy instrument is set to meet the target exactly unless the ZLB binds. Yet another extension would be the implications of transparency about the policy rule to the properties of learning dynamics.

It should also be noted that these results about the key role of forward guidance have been obtained by comparing the properties of the different regimes when dynamics arise from learning. We have not formally modelled the dynamics that would follow after a shift from one regime to another. Analysis of how and why private agents might change their forecasting practice after the introduction of a new regime would be well worth studying and we plan to do this in the future. Central bank policies can probably influence this change of forecasting and this should be analyzed.

There are naturally numerous more applied concerns that should be investigated. We just mention the issues connected with measurement and fluctuations of output and productivity. The measurement problems in output and output gap are discussed by (Orphanides 2003) and (Orphanides and Williams 2007). (Hall and Mankiw 1994) emphasize that the volatility in output and productivity measures can pose challenges to nominal GDP targeting in particular. Our non-stochastic model does not address these concerns. We plan to address some of these extensions in the future.
Notes

1For prominent early analyses, see e.g. (Krugman 1998), (Eggertsson and Woodford 2003), and (Svensson 2003). (Werning 2012) is a recent paper on optimal policies in a liquidity trap under rational expectations.

2For discussions of forward guidance see e.g. (Woodford 2012), (Campbell, Evans, Fisher, and Justiniano 2012), (Filardo and Hoffmann 2014), (Bayomi 2014), (Gavin, Keen, Richter, and Throckmorton 2014) and (Weale 2013).

3Price-level targeting has received a fair amount of attention, see for example (Svensson 1999) and (Vestin 2006). Nominal income targeting has been considered, for example (Hall and Mankiw 1994), (Jensen 2002) and (Mitra 2003). A recent overview of nominal income targeting is in (Bean 2009).

4A switch in the policy regime is one reason for assuming that private agents’ knowledge is imperfect and agents need to learn the new economic environment.

5For discussion and analytical results concerning adaptive learning in a wide range of macroeconomic models, see for example (Sargent 1993), (Evans and Honkapohja 2001), (Sargent 2008), and (Evans and Honkapohja 2009b).

6Some aspects of imperfect knowledge are included in the discussion of price-level targeting by (Gaspar, Smets, and Vestin 2007). See also the literature they cite.

7(Williams 2010) makes a similar argument about price-level targeting under imperfect knowledge and learning. His work relies on simulations of a linearized model with a single steady state.

8The same framework is developed in (Evans, Guse, and Honkapohja 2008). It is also employed in (Evans and Honkapohja 2010) and (Benhabib, Evans, and Honkapohja 2014).

9Details are given in the online appendix. They are based on (Benhabib, Evans, and Honkapohja 2014).

10See (Evans and Honkapohja 2010) for an explanation as to why inflation does not also depend directly on the expected future aggregate inflation rate in the Phillip’s curve relationship (9). There is an indirect effect of expected
inflation on current inflation via current output.

11(Evans, Honkapohja, and Mitra 2012) state the assumptions under which Ricardian Equivalence holds along a path of temporary equilibria with learning if agents have an infinite decision horizon.

12See (Evans and Honkapohja 1998) or (Evans and Honkapohja 2001), Section 7.2 for discussions of learning in deterministic and stochastic models.

13In the literature, PLT is sometimes advocated as a way to achieve optimal policy with timeless perspective under RE locally near the targeted steady state. The learnability properties of this form of PLT depend on the implementation of the corresponding interest rate rule, see (Evans and Honkapohja 2013), section 2.5.2 for an overview and further references. Global properties of this case have not been analyzed.

14The ZLB and multiple equilibria for an inflation targeting framework and a Taylor-type interest rate rule has been analyzed in (Reifschneider and Williams 2000), (Benhabib, Schmitt-Grohe, and Uribe 2001) and (Benhabib, Schmitt-Grohe, and Uribe 2002). These issues have been considered under learning, e.g., in (Evans and Honkapohja 2010), and (Benhabib, Evans, and Honkapohja 2014). Existence of the two steady states under PLT was pointed out in (Evans and Honkapohja 2013), section 2.5.3.

15In what follows $\hat{\mathbb{E}} = 1$ is taken as a steady state equilibrium. In principle, we then need to impose a finite satiation level in money demand or assume that the lower bound is slightly above one, say $\hat{R} = 1 + \varepsilon$. Neither of these assumptions is explicitly used below as our focus is on inflation and output dynamics.

16Mathematica routines for the numerical analysis and for technical derivations in the theoretical proofs are available upon request from the authors.

17Forward guidance in the form of announcements of the future path of the interest rate is studied from the learning viewpoint in (Cole 2014) and (Gauss 2014).

18Note that $\tau X_{t+1}^{e} = X_{t}^{e}$ in more detailed notation.

19In the PLT case, equation (26) becomes $0 = 0$ in the limit as $\tau X_{t}^{e}, X_{t}^{e} \to 0$, so that inflation expectations are not defined by the equation. They are
instead given by the steady state condition $\pi^e_t = \beta$.

In Propositions 4 and 5 expectational stability means local stability for all $\omega, \omega_1 \in (0, \bar{\omega})$ for some $\bar{\omega} > 0$.

The truncation is done to avoid the possibility of infinite consumption levels for some values of the expectations. See (Evans and Honkapohja 2010) for more details.

(Judd and Motley 1993) suggest this number once we note that they use an annualized growth and quarterly interest rate measures. We are not aware of any recent calibration for $\nu$.

We remark that Proposition 6 does not hold for $\gamma = 0$ when $\omega_1 \rightarrow 1$, but it does hold for the calibrated values for which $\gamma > 0$.

PLT and NGDP rules yield identical dynamics under the ZLB if the initial conditions are identical. From (26) and (29) we get for PLT $\pi^e_t = p_t (\pi^* \nu_{t-1})^{-1}$ and for NGDP $\pi^e_t = p_t (\Delta \bar{\nu}_{t-1})^{-1}$, which are the same as $\Delta \bar{\varepsilon} = \pi^*$.

This result is in contrast to inflation targeting studied in (Evans, Guse, and Honkapohja 2008) and (Evans and Honkapohja 2010). We aim to explore this phenomenon further in a more realistic (stochastic) model.

(Preston 2008) discusses local learnability of the targeted steady state with IH learning when the central bank employs PLT. In the earlier literature (Evans and Honkapohja 2006) and (Evans and Honkapohja 2013) consider E-stability of the targeted steady state under Euler equation learning for versions of PLT.

Convergence is relatively fast for NGDP and PLT with the baseline gain while it is slow for IT. Hence, we use a gain of 0.01 to get faster convergence with IT.

This approach is similar in spirit to the commonly used impulse response analysis for stochastic models, except that shocks are not normalized to have unit variance and expectations are formed via learning.

(Vestin 2006) argues that under RE optimal IT policy under discretion performs worse than optimal PLT policy under discretion in a NK model. (Jensen 2002) compares IT and NGDP targeting for optimal discretionary and commitment policies under RE.
This means that mean paths for inflation and output start from initial values that are above the corresponding steady state values. This delivers genuine adjustment dynamics.

The NGDP regime is also solved analogously; (12), (13) are solved for \( \pi \) and \( y \) given (21) and (25) and correspondingly for the IT regime.

The relative comparison of PLT and NGDP seems to be sensitive to the values of the policy rule parameters but the comparison of IT to these two is not. Details are available on request.

This can be seen e.g. from constructing in the \((\pi, y)\)- or \((\pi^e, y^e)\)-space line plots for path for the same initial conditions in the two cases. Details are available on request.

The assumption \( \omega_1 = 1 \) plays a role here. Small values of \( \omega_1 \) would make convergence more gradual.

REFERENCES

A Derivation of the Phillips Curve

Starting with (6), let

\[ Q_{t,s} = (\pi_{t,s} - 1) \pi_{t,s}. \]  

The appropriate root for given \( Q \) is \( \pi \geq \frac{1}{2} \) and so we need to impose \( Q \geq -\frac{1}{4} \) to have a meaningful model. Using the production function \( h_{t,s} = y_{t,s}^{1/\alpha} \) we can rewrite (6) as

\[ Q_{t,s} = \left( \frac{\nu}{\alpha \gamma} \right) y_{t,s}^{(1+\epsilon)/\alpha} - \frac{\nu - 1}{\gamma} y_t^{1/\nu} y_{t,s}^{(\nu - 1)/\nu} c_{t,s}^{\gamma_1} + \beta E_{t,s} Q_{t+1,s}, \]

and using the demand curve \( y_{t,s}/y_t = (P_{t,s}/P_t)^{-\nu} \) gives

\[ Q_{t,s} = \left( \frac{\nu}{\alpha \gamma} \right) (P_{t,s}/P_t)^{-\nu} y_{t,s}^{(1+\epsilon)/\alpha} - \frac{\nu - 1}{\gamma} y_t (P_{t,s}/P_t)^{-\nu} c_{t,s}^{\gamma_1} + \beta E_{t,s} Q_{t+1,s}. \]

Defining

\[ x_{t,s} \equiv \left( \frac{\nu}{\alpha \gamma} \right) (P_{t,s}/P_t)^{-\nu} y_{t,s}^{(1+\epsilon)/\alpha} - \frac{\nu - 1}{\gamma} y_t (P_{t,s}/P_t)^{-\nu} c_{t,s}^{\gamma_1}, \]

and iterating the Euler equation yields

\[ Q_{t,s} = x_{t,s} + \sum_{j=1}^{\infty} \beta^j E_{t,s} x_{t+j,s}, \]

provided that the transversality condition

\[ \beta^j E_{t,s} x_{t+j,s} \rightarrow 0 \text{ as } j \rightarrow \infty \]

holds. It can be shown that the condition (A4) is an implication of the necessary transversality condition for optimal price setting. For further details see (Benhabib, Evans, and Honkapohja 2014).

The variable \( x_{t+j,s} \) is a mixture of aggregate variables and the agent’s

40
own future decisions. Nonetheless this equation for $Q_{t,s}$ can be the basis for decision-making as follows. So far we have only used the agent’s price-setting Euler equation and the above limiting condition (A4). We now make some further adaptive learning assumptions.

First, agents are assumed to have point expectations, so that their decisions depend only on the mean of their subjective forecasts. Second, we assume that agents have learned from experience that in fact, in temporary equilibrium, it is always the case that $\Pi_{t,s} = \Pi_t = 1$. Therefore we assume that agents impose this in their forecasts in (A3), i.e. they set $(P_{t+j,s}/P_{t+j})^e = 1$. Third, agents have learned from experience that in fact, in temporary equilibrium, it is always the case that $\Pi_{t,s} = \Pi_t = 1$. Therefore we assume that agents impose this in their forecasts in (A3), i.e. they set $(P_{t+j,s}/P_{t+j})^e = 1$. Third, agents have learned from experience that in fact, in temporary equilibrium, it is always the case that $c_{t,s} = y_t - g_t$ in per capita terms. Therefore, agents impose in their forecasts that $c_{t+j,s} = y_{t+j} - g_{t+j}$. In the case of no fiscal policy change this becomes $c_{t+j,s} = y_{t+j} - \bar{g}$.

We now make use of the representative agent assumption, so that all agents have the same utility functions, initial money and debt holdings, and prices. We assume also that they make the same forecasts as well as forecasts of other variables that will become relevant below. Under these assumptions all agents make the same decisions at each point in time, so that $h_{t,s} = h_t$, $y_{t,s} = y_t$, $c_{t,s} = c_t$ and $\pi_{t,s} = \pi_t$, and all agents make the same forecasts. For convenience, the utility of consumption and of money is also taken to be logarithmic ($\sigma_1 = \sigma_2 = 1$). Then (A3) takes the form

\begin{align*}
(A5) \quad Q_t &= \frac{\nu}{\alpha \gamma} y_t^{(1+\epsilon)/\alpha} - \frac{\nu - 1}{\gamma} y_t (y_t - \bar{g})^{-1} + \\
&\quad \frac{\nu}{\gamma} \sum_{j=1}^{\infty} \alpha^{-1} \beta^j \left( y_{t+j}^e \right)^{(1+\epsilon)/\alpha} - \frac{\nu - 1}{\gamma} \sum_{j=1}^{\infty} \beta^j \left( \frac{y_{t+j}}{y_{t+j} - \bar{g}} \right) \\
&\equiv \tilde{K}(y_t, y_{t+1}, y_{t+2} \ldots). 
\end{align*}

B Derivation of the Consumption Function

To derive the consumption function from (7) we use the flow budget constraint and the NPG condition to obtain an intertemporal budget con-
straint. First, we define the asset wealth

\[ a_t = b_t + m_t \]

as the sum of holdings of real bonds and real money balances and write the flow budget constraint as

(B1) \[ a_t + c_t = y_t - Y_t + r_t a_{t-1} + \pi_t^{-1} (1 - R_{t-1}) m_{t-1}, \]

where \( r_t = R_{t-1}/\pi_t \). Note that we assume \((P_{jt}/P_t)y_{jt} = y_t\), in view of the representative agent assumption. Iterating (B1) forward and imposing

(B2) \[ \lim_{j \to \infty} (D^e_{t,t+j})^{-1} a^e_{t+j} = 0, \]

where

\[ D^e_{t,t+j} = \frac{R_t}{\pi_{t+1}} \prod_{i=2}^{j} \frac{R^e_{t+i-1}}{\pi^e_{t+i}} \]

with \( r^e_{t+i} = \frac{R^e_{t+i-1}}{\pi^e_{t+i}} \), we obtain the life-time budget constraint of the household

(B3) \[ 0 = r_t a_{t-1} + \Phi_t + \sum_{j=1}^{\infty} (D^e_{t,t+j})^{-1} \Phi^e_{t+j} \]

(B4) \[ = r_t a_{t-1} + \phi_t - c_t + \sum_{j=1}^{\infty} (D^e_{t,t+j})^{-1} (\phi^e_{t+j} - c^e_{t+j}), \]

where

(B5) \[
\begin{align*}
\Phi^e_{t+j} &= y^e_{t+j} - Y^e_{t+j} - c^e_{t+j} + (\pi^e_{t+j})^{-1} (1 - R^e_{t+j-1}) m^e_{t+j-1}, \\
\phi^e_{t+j} &= \Phi^e_{t+j} + c^e_{t+j} = y^e_{t+j} - Y^e_{t+j} + (\pi^e_{t+j})^{-1} (1 - R^e_{t+j-1}) m^e_{t+j-1}.
\end{align*}
\]

Here all expectations are formed in period \( t \), which is indicated in the notation for \( D^e_{t,t+j} \) but is omitted from the other expectational variables.

Invoking the relations

(B6) \[ c^e_{t+j} = c_t \beta^j D^e_{t,t+j}; \]
which is an implication of the consumption Euler equation (7), we obtain

$$(B7)\quad c_t(1-\beta)^{-1} = r_t a_{t-1} + y_t - \Upsilon_t + \pi_t^{-1}(1-R_{t-1})m_{t-1} + \sum_{j=1}^{\infty}(D_{t,t+j}^e)^{-1}\phi_{t+j}^e.$$ 

As we have $\phi_{t+j}^e = y_{t+j}^e - \Upsilon_{t+j}^e + (\pi_{t+j}^e)^{-1}(1-R_{t+j-1}^e)m_{t+j-1}^e$, the final term in (B7) is

$$\sum_{j=1}^{\infty}(D_{t,t+j}^e)^{-1}(y_{t+j}^e - \Upsilon_{t+j}^e) + \sum_{j=1}^{\infty}(D_{t,t+j}^e)^{-1}(\pi_{t+j}^e)^{-1}(1-R_{t+j-1}^e)m_{t+j-1}^e$$ 

and using (8) we have

$$\sum_{j=1}^{\infty}(D_{t,t+j}^e)^{-1}(\pi_{t+j}^e)^{-1}(1-R_{t+j-1}^e)m_{t+j-1}^e = \sum_{j=1}^{\infty}(D_{t,t+j}^e)^{-1}(\pi_{t+j}^e)^{-1}(1-R_{t+j-1}^e)c_{t+j-1}^e = -\frac{\chi\beta}{1-\beta}c_t.$$ 

We obtain the consumption function

$$c_t \frac{1 + \chi\beta}{1-\beta} = r_t b_{t-1} + \frac{m_{t-1}}{\pi_t} + y_t - \Upsilon_t + \sum_{j=1}^{\infty}(D_{t,t+j}^e)^{-1}(y_{t+j}^e - \Upsilon_{t+j}^e).$$ 

So far it is not assumed that households act in a Ricardian way, i.e. they have not imposed the intertemporal budget constraint (IBC) of the government. To simplify the analysis, we assume that consumers are Ricardian, which allows us to modify the consumption function as in (Evans and Honkapohja 2010). (We remark that (Evans, Honkapohja, and Mitra 2012) state the conditions under which Ricardian Equivalence holds along a path of temporary equilibria with learning if agents have an infinite decision horizon.)
From (4) one has

\[ b_t + m_t + \Upsilon_t = \bar{g} + m_{t-1}\pi^{-1}_t + r_t b_{t-1} \] or
\[ b_t = \Delta_t + r_t b_{t-1} \]
\[ \Delta_t = \bar{g} - \Upsilon_t - m_t + m_{t-1}\pi^{-1}_t. \]

By forward substitution, and assuming
\[ \lim_{T \to \infty} D_{t,t+T}b_{t+T} = 0, \]
we get
\[ 0 = r_t b_{t-1} + \Delta_t + \sum_{j=1}^{\infty} D_{t,t+j}^{-1} \Delta_{t+j}. \]

Note that \( \Delta_{t+j} \) is the primary government deficit in \( t + j \), measured as government purchases less lump-sum taxes and less seigniorage. Under the Ricardian Equivalence assumption, agents at each time \( t \) expect this constraint to be satisfied, i.e.

\[ 0 = r_t b_{t-1} + \Delta_t + \sum_{j=1}^{\infty} (D_{t,t+j}^e)^{-1} \Delta_{t+j}^e, \] where
\[ \Delta_{t+j}^e = \bar{g} - \Upsilon_{t+j}^e - m_{t+j} + m_{t+j-1}^e(\pi_{t+j}^e)^{-1} \text{ for } j = 1, 2, 3, \ldots. \]

A Ricardian consumer assumes that (B8) holds. His flow budget constraint (B1) can be written as:

\[ b_t = r_t b_{t-1} + \psi_t, \text{ where} \]
\[ \psi_t = y_t - \Upsilon_t - m_t - c_t + \pi^{-1}_t m_{t-1}. \]

The relevant transversality condition is now (B8). Iterating forward and using (B6) together with (B8) yields the consumption function

\[ c_t = (1 - \beta) \left( y_t - \bar{g} + \sum_{j=1}^{\infty} (D_{t,t+j}^e)^{-1} (y_{t+j}^e - \bar{g}) \right). \]
C Other Details

In temporary equilibrium the bond dynamics and money demand are

1. Bond dynamics

\[ b_t + m_t = g - \Upsilon_t + \frac{R_{t-1}}{\pi_t} b_{t-1} + \frac{m_{t-1}}{\pi_t}. \]  

(C1)

2. Money demand

\[ m_t = \chi \beta R_t \frac{R_t}{R_t - 1} c_t. \]  

(C2)

In general \( b_{t-1}, m_{t-1}, \) and \( R_{t-1} \) are state variables but, as noted in the text, with the Ricardian assumption they can be dropped in inflation, output and interest rate dynamics.

D Proofs of Theoretical Results

Proof of Proposition 1: (a) Consider the interest rate rule (20). Imposing \( \hat{\pi} = \beta < 1 \) implies that \( P_t \to 0 \) while \( \bar{P}_t \to \infty \) (or \( \bar{P} \) if \( \pi^* = 1 \)) as \( t \to \infty \). It follows that \( \bar{R} - 1 + \psi_y[(P_t - \bar{P}_t)/\bar{P}_t] + \psi_y[(y_t - y^*)/y^*] < 0 \) for \( t \) sufficiently large when \( y_t \to \hat{y} < y^* \), so that \( R_t = 1 \) in the interest rate rule. A unique steady state satisfying (22) is obtained. Thus, \( \hat{y}, \hat{\pi} \) and \( \bar{R} \) constitute a ZLB-constrained steady state.

(b) Now consider the economy under NGDP targeting and impose \( \hat{R} = 1, \hat{\pi} = \beta, \) and \( y = \hat{y} \) where \( \hat{y} \) solves (22) with \( \hat{\pi} = \beta \). Again \( P_t \to 0 \) while \( \bar{P}_t \to \infty \) or \( \bar{P} \) if \( \pi^* = 1 \) as \( t \to \infty \). Inside the interest rate rule (21) we have

\[ (P_t y_t - \bar{z}_t)/\bar{z}_t = (P_t/\bar{P}_t)(\hat{y}/y^*) - 1 \to -1, \]

so that for large enough \( t \) the interest rate from (21) must be \( R_t = 1 \). These requirements yield a steady state state for the economy. \( \blacksquare \)

We next derive expectational stability and instability results for the steady states by linearizing the system (23)-(24) around a steady state.
Linearize first (23):

\[
(D1) \quad x_t = (-DF_x)^{-1}(DF_{xx}x_t^e + DF_{x_{t-1}}x_{t-1}) \equiv Mx_t^e + Nx_{t-1},
\]

where for brevity we use the same notation for deviations from the steady state. Recall that \(x_t^e\) refers to the expected future values of \(x\), and not the current one. Combining (D1) and (24) we get the system

\[
(D2) \quad \begin{pmatrix} x_t \\ x_t^e \end{pmatrix} = \begin{pmatrix} N + \omega M & (1 - \omega)M \\ \omega I & (1 - \omega)I \end{pmatrix} \begin{pmatrix} x_{t-1} \\ x_{t-1}^e \end{pmatrix}.
\]

As mentioned in the text, we are interested in "small gain" results, i.e. stability obtains for all \(\omega\) sufficiently close to zero. The first two results rely on the E-stability method discussed in (Evans and Honkapohja 2001) while some of the later results are based on the direct analysis of system (D1) and (D2).

**Stability Results for the IT Regime**

**Proof of Proposition 2:** In the limit \(\gamma \to 0\) the coefficient matrices take the form \(N = 0\) and

\[
M = \begin{pmatrix} \frac{\beta}{\beta-1} & 0 & 0 \\ \frac{\pi^*y^* + (y^* - \bar{y})\beta^2\psi_\pi}{y^*(\bar{y} - y^*)(\beta-1)\psi_\pi} & \frac{1}{(1-\beta)\beta\psi_\pi} & \frac{\beta}{(\beta-1)\beta\psi_\pi} \\ \frac{\pi^*}{(\bar{y} - y^*)(\beta-1)\beta} & \frac{1}{\beta(1-\beta)} & \frac{\beta}{\beta-1} \end{pmatrix},
\]

so that the system is forward-looking. The equation for \(y_t\) has the form

\[
y_t = \frac{\beta}{\beta - 1} y_t^e,
\]

which is E-stable and does not contribute to possible instability of the remaining \(2 \times 2\) system for which the coefficient matrix \(\tilde{M}\) is the bottom right corner of \(M\). It is easily verified that the both eigenvalues of matrix \(\tilde{M} - I\) have negative real parts. Its determinant is

\[
Det(\tilde{M} - I) = \frac{\beta\psi_\pi - \pi^*}{(1 - \beta)\beta\psi_\pi},
\]

46
so the determinant is positive if and only if $\psi_\pi > \pi^*/\beta = \bar{R}$. Its trace is

$$Tr(\tilde{M} - I) = -Det(\tilde{M} - I) - 1.$$ 

The result follows. ■

**Proof of Proposition 3**: When the ZLB binds, the interest rate $R_t$ is constant and $R_t^e$ converges to this value independently of the other equations. Moreover, with $R_t$ constant, $X_t$ has no influence on $y_t$ and $\pi_t$. The temporary equilibrium system and learning dynamics then reduce to two variables $y_t$ and $\pi_t$ together with their expectations. Moreover, no lags of these variables are present, so that the abstract system (D1) has only two state variables $x_t = (y_t, \pi_t)^T$ and with $N = 0$ it can be made two dimensional. We analyze this by usual E-stability method.

It can be shown that

$$Det(M - I) = \frac{\hat{y}^{(1+\varepsilon)/\alpha}(1+\varepsilon)\nu(\bar{g} - \hat{y})^2 + \bar{g}\hat{y}\alpha^2(\nu - 1)}{(\bar{g} - \hat{y})\hat{y}\alpha^2(\beta - 1)^2\beta(2\beta - 1)\gamma}.$$ 

The numerator is positive whereas the denominator is negative. Thus, $Det(M - I) < 0$, which implies E-instability (in fact the steady state is saddle path stable as shown in (Evans and Honkapohja 2010)). ■

**Price-Level Targeting with Forward Guidance**

**Proof of Proposition 4**: With the state variable $x_t = (y_t, \pi_t, R_t, X_{t,t}, X_t^e)^T$, the learning system can be written in the standard form (D2). In the limit $\gamma \to 0$ the coefficient matrices are

$$M = \begin{pmatrix}
\pi^* & 0 & 0 & 0 & 0 \\
\frac{\beta}{y^*(\bar{g} - \hat{y})^2\psi_y} & 0 & \frac{\pi^*\beta}{(\beta - 1)\beta\psi_y} & \frac{(\pi^*)^2}{(1-\beta)\beta\psi_y} & 0 \\
0 & \frac{\beta - 1}{\beta} & \bar{g} & (1-\beta)\beta & 0 \\
0 & \frac{\beta - 1}{\beta} & \bar{g} & (1-\beta)\beta & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix}$$

and

$$\bar{M} = \begin{pmatrix}
\pi^* & 0 & 0 & 0 & 0 \\
\frac{\beta}{y^*(\bar{g} - \hat{y})^2\psi_y} & 0 & \frac{\pi^*\beta}{(\beta - 1)\beta\psi_y} & \frac{(\pi^*)^2}{(1-\beta)\beta\psi_y} & 0 \\
0 & \frac{\beta - 1}{\beta} & \bar{g} & (1-\beta)\beta & 0 \\
0 & \frac{\beta - 1}{\beta} & \bar{g} & (1-\beta)\beta & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix}.$$ 

47
Of the eigenvalues for the coefficient matrix of (D2) three are equal to zero, three equal 1$-\omega$ and one equals $(1-\beta-\omega)/(\beta-1)$. All these roots are inside the unit circle for all $\omega > 0$ sufficiently small. The three remaining roots are those of a cubic equation $\lambda^3+a_2\lambda^2+a_1\lambda+a_0=0$. The Schur-Cohn conditions are $SC1=1+a_1+|a_0+a_2|>0$ and $SC2=1-a_0^2-|a_1-a_0a_2|>0$. In the limit $\omega \to 0$ and $\omega_1 \to 0$ we have $a_0=0$, $a_1=(\beta \psi_p)^2$, $a_0+a_2=-2(\beta \psi_p)^2$ and $a_1-a_0a_2=(\beta \psi_p)^2$, so that $SC1$ and $SC2$ are positive for sufficiently small positive $\omega$ and $\omega_1$ when $(\beta \psi_p)^2 < 1$. \[\text{Nominal GDP Targeting with Forward Guidance}\]

**Proof of Proposition 5:** With the state variable $x_t = (y_t, \pi_t, R_t, Y_{t,t}, Y_{t}^e, y_{t}^e)^T$, the learning system can be written in the standard form (D2). In the limit $\gamma \to 0$ the coefficient matrices are

\[
N = \begin{pmatrix}
0 & 0 & \frac{\pi^*(\pi^*\omega_1-(\beta-1)\beta \psi_p)}{(\beta-1)\beta \psi_p} & 0 & \frac{(\pi^*)^2(1-\omega_1)}{(\beta-1)\beta \psi_p} \\
0 & 0 & \frac{\pi^*(\omega_1)}{(\beta-1)\beta \psi_p} & 0 & \frac{\pi^*(1-\omega_1)}{(\beta-1)\beta \psi_p} \\
0 & 0 & \frac{\omega_1}{(\beta-1)\beta \psi_p} & 0 & \frac{\pi^*(1-\omega_1)}{(\beta-1)\beta \psi_p} \\
0 & 0 & 1-\omega_1 & 0 & 0
\end{pmatrix}.
\]

The system has four eigenvalues equal to zero, four eigenvalues equal to
1 − ω, one eigenvalue equal to 1 − ω₁, one eigenvalue equal to 1 − ω/(1 − β), and the two eigenvalues that are roots of the quadratic \( \lambda^2 + a_1 \lambda + a_0 = 0 \). It can be shown that the Schur-Cohn conditions are satisfied for all sufficiently small \( \omega \) and \( \omega_1 \) provided \( \psi > \pi^*(1 - \beta)/\beta \). ■

Price-Level Targeting without Forward Guidance

Proof of Proposition 6: In the limit \( \gamma \to 0 \) for (D1) we have the coefficient matrices

\[
M = \begin{pmatrix}
\frac{\beta}{\beta - 1} & 0 & 0 & 0 & 0 \\
\frac{\pi^*(\pi^*g^*(\psi^* - \bar{g})\beta \psi_p)}{\psi^*(\bar{g} - g^*)(\beta - 1)\beta \psi_p} & \frac{\pi^* \beta}{(1 - \beta) \beta \psi_p} & \frac{\pi^* \beta}{(1 - \beta) \beta \psi_p} & 0 & 0 \\
\frac{\pi^* \beta}{(1 - \beta) \beta \psi_p} & 0 & \frac{1}{\beta (1 - \beta)} & \frac{\beta}{\beta - 1} & 0 \\
\frac{\pi^* \beta}{(1 - \beta) \beta \psi_p} & 0 & 0 & \frac{1}{\beta (1 - \beta) \psi_p} & 0 \\
\pi^* \beta & 0 & 0 & 0 & 0 \\
\end{pmatrix}, \quad N = \begin{pmatrix}
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & -\pi^* \\
0 & 0 & 0 & 0 & 0 \\
\end{pmatrix}.
\]

It is seen that in the limit \( \gamma \to 0 \) the equation for \( y_t \) is simply

\[
y_t = \frac{\beta}{\beta - 1} y_t^e,
\]

so that the movement of \( y_t \) under learning influences other variables but not vice versa. With learning rule (15) there is convergence to the steady state when \( \omega \) is sufficiently small.

We can eliminate the sub-system for \( y_t \) and \( y_t^e \) from (D2). We can also eliminate the equation for expectations of \( X_t \) since they do not appear in the system. This makes the system five-dimensional. Computing the characteristic polynomial it can be seen that it two roots equal to 0 and one root equal to \( 1 - \omega \). The roots of the remaining quadratic equation, written symbolically as \( \lambda^2 + a_1 \lambda + a_0 = 0 \), are inside the unit circle provided that

\[
SC0 = 1 - |a_0| > 0, \\
SC1 = 1 + a_0 - |a_1| > 0.
\]

It can be computed that \( a_0 = -\pi^* \omega/[(\beta - 1)\beta \psi_p] \) and so \( SC0 > 0 \) for sufficiently small \( \omega > 0 \). For the second condition, it turns out that \( SC1 = 0 \).
when \( \omega = 0 \) and \( \partial SC1 / \partial \omega = 1 / (1 - \beta) \), which is positive. ■

Nominal GDP Targeting without Forward Guidance

Now the state variable is \( x_t = (y_t, \pi_t, R_t, Y_t)^T \).

**Proof of Proposition 7:** In the case \( \gamma \to 0 \) the coefficient matrices are given by

\[
M = \begin{pmatrix}
\frac{\beta}{\beta - 1} & \pi^* & 0 & 0 \\
\frac{\beta}{\beta - 1} & \frac{\pi^*}{1 - \beta} & \frac{\pi^* \beta}{(\beta - 1) \psi} & 0 \\
\frac{\beta}{\beta - 1} & \frac{1}{(1 - \beta) \psi} & \frac{\beta - 1}{\beta} & 0 \\
\frac{\beta}{\beta - 1} & \frac{1}{(1 - \beta) \psi} & \frac{\beta - 1}{(\beta - 1) \psi} & 0
\end{pmatrix},
\quad N = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & -\pi^* \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{pmatrix}.
\]

Repeating the method used in the proof of Proposition 6, again the sub-system for \( y_t \) is independent from the other equations and expectations of \( \pi_t \) do not appear in the system. Eliminating the three equations one again obtains a five-dimensional system. Its characteristic polynomial has two roots equal to 0, one root equal to \( 1 - \omega \), while the remaining roots satisfy a quadratic equation. The roots can be shown to be real and lie in the interval \((-1, 1)\) for all sufficiently small \( \omega > 0 \). ■

**E Further Material**

The domain of attraction of PLT with forward guidance is given here.
It is seen that the domain of attraction covers the whole area above values $\phi_0 = 0.94$, except the unstable low steady state where $X_0 = X_0^e = 0$. In fact, the initial value for $\phi_0$ can be lower than 0.94 but with these initial conditions learning becomes slow which makes the numerical computations quite involved.

**Dynamics of Adjustment without Forward Guidance**

Figure A.2 illustrates the dynamics of inflation, output and the interest rate when there is no forward guidance. The runs for all the grid points for $\pi_0^e$ and $y_0^e$ are done for a time interval of 500 periods and the mean values of the endogenous variables are reported. The figure shows the mean paths of these variables for the first 200 periods.
We first explain the movements in the PLT paths. The $R_t$ path is broadly speaking driven by the dynamics of $X_t$ (not shown in the figures). The PLT interest rule (20) responds to both percentage deviations in $X_t$ and $y_t$ but the former effect dominates because it is much larger in quantitative terms. Initially by period 12, (mean) relative prices $X_t$ increase gradually to almost 1.5% above its steady state value (of one) while $y_t$ falls by just over 0.1%; $R_t$ therefore rises gradually to almost 0.2% by period 12. Thereafter, till around period 40, $y_t$ increases gradually above its (desired) steady state value. However, during this period relative prices $X_t$ fall monotonically till they are almost 1% below its steady state value. This moves $R_t$ on a downward path during this period. Then, $X_t$ increases monotonically driving $R_t$ upwards. Note that $X_t$ increases over time if $\pi_t$ is above the target $\pi^*$ (and decreases otherwise; see equation (25) later). These damped oscillations in $X_t$ and $R_t$ continue with the amplitude diminishing over time leading to gradual convergence as shown in the figures.
There are also damped oscillations in $y_t$ and $\pi_t$ as they converge towards the steady state. The movements in $y_t$ can be understood from the movements in nominal interest rates. With initial inflation above target, $X_t$ increases which increases $R_t$ as mentioned previously. The increase in $R_t$ reduces $y_t$ and $\pi_t$ till around period 12. By then $\pi_t$ is below target which causes $X_t$ and $R_t$ to decline. This raises $y_t$ through the aggregate demand channel. However, output expectations $y_t^e$ continue to fall for several more periods since they move slowly over time in response to actual $y_t$. This causes $\pi_t$ to continue to fall till around period 20 despite $y_t$ rising during this time since the effect from $y_t^e$ dominates the movement in $y_t$ as the effect from $y_t^e$ arises from a projection into the infinite future as reflected by the coefficient $\beta/(1-\beta)$ in (14). Eventually, the rising path of $y_t$ puts $y_t^e$ and hence $\pi_t$ on an upward path. In general, movements in $\pi_t$ lag behind movements in $y_t$ for PLT. From period 20 to 40, both $y_t$ and $\pi_t$ are increasing. Then $y_t$ starts falling due to rising $R_t$ (which in turn is due to rising $X_t$ because of inflation being above the target level $\pi^*$) while $\pi_t$ continues to rise till around period 50 due to the dominant rising output expectations. Eventually, again falling $y_t$ lowers $y_t^e$ which in turn lowers $\pi_t$. These oscillations in $y_t$, $\pi_t$ and $R_t$ continue (with movements in $\pi_t$ lagging behind those in $y_t$) as they converge towards the steady state.

These movements in the $(\pi_t, y_t)$ space are illustrated in Figure A.3 which plots the first 200 periods for one particular simulation with PLT when initial $y_0^e = 0.9431$ and $\pi_0^e = \pi^*$ and all other variables are as in Figure A.2. Over time the oscillations in $y_t$, $\pi_t$ and $R_t$ dampen and the forecasts $\pi_t^e$, $y_t^e$ and $R_t^e$ converge to the steady state values. However, since $\pi_t^e$, $y_t^e$ and $R_t^e$ change slowly, the oscillations in $y_t$, $\pi_t$ and $R_t$ take time to dampen and convergence to the steady state is slow.
Figure A.3: Cyclical fluctuations in $y_t$ and $\pi_t$ as they converge towards the steady state for PLT without forward guidance shown for the first 200 periods with one particular initial point.

Under NGDP, a similar phenomenon is present with deviations in GDP $P_t y_t / \bar{z}$ from the target value driving the dynamics of $R_t$ by the rule (21). Deviations in GDP from the target value are oscillatory initially increasing till around period 10 putting $R_t$ on an upward path. Thereafter, $P_t y_t / \bar{z}_t$ moves on a downward path putting $R_t$ on a downward path. The oscillations gradually dampen over time leading to eventual convergence. The movements in $y_t$ and $\pi_t$ are also oscillatory as they converge towards the steady state as is evident in Figure A.2.

In sharp contrast, the dynamics of $y_t, \pi_t$ and $R_t$ under IT are all monotonic after the initial jump. As $R_t$ falls, real interest rates fall because of the active Taylor rule which puts $y_t$ on a monotonic upward path (after the initial fall) through the aggregate demand channel. However, the low output in the initial period makes output expectations pessimistic for the entire future; this effect dominates and puts inflation on a downward monotonic path through the Phillips curve.

Dynamics of Adjustment with Forward Guidance

Figure A.4 illustrates the dynamics of inflation, output and the interest rate $\pi, y, and R$ for IT, PLT and NGDP targeting with forward guidance
incorporated for the latter two regimes. (The mean paths under IT are the same as in Figure A.2 and are included to facilitate comparisons.) In PLT we simulate the model for various values of $y_0^c$ and $X_0^c$; the range for $y_0^c$ is the same as under IT while that for $X_0^c$ is between 0.9975 and 1.0025 (i.e. within 1% of its annual steady state value) at intervals of 0.0002 and $R_0^c = R_0 = \bar{R}$. The initial relative price is set at $X_0 = X_0^c + 0.0001$. For NGDP we simulate the model for various values of $y_0^c$ and $Y_0^c$; the range for $y_0^c$ is again the same as under IT while that for $Y_0^c$ is between 0.9975 and 1.0025 at intervals of 0.0005. Initial relative price or output expectations under PLT or NGDP are allowed to vary 1% around its annual steady state values to make it consistent with the fluctuations of inflation expectations under IT which is also around 1% annually. The initial relative output is set at $Y_0 = Y_0^c + 0.0001$. Again we operationalize the ZLB of the interest rate by setting the lower bound to 1.0001. The runs are done for a period of 500 periods and the mean values of the endogenous variables are reported. The figures show the mean paths of these variables for the first 100 periods.
Figure A.4: Inflation, output and interest rate mean dynamics under IT, PLT, and NGDP (the latter two under gap forecasting). IT in dashed, NGDP in solid and PLT in mixed dashed line. The horizontal dashed line is the steady state. Note that the paths under PLT and NGDP converge quite fast.

We remark that properties of the dynamics in Figure A.4 and Table 2 in the main text are affected if agents form expectations as a weighted average of $X_{t-1}$ and $X_{t-1}^e$. The domain of attraction results in Figure 2 mostly go through.

Details on Volatility Computations

In Tables 1 and 2 the *ex post* utility is computed from the formula

$$
\sum_{t=0}^{T_{end}} \beta^t U_t,
$$

where

$$
U_t = \ln[y_t - g] + \chi \ln[\frac{\beta \chi R_{t-1}(y_{t-1} - g)}{(R_{t-1} - 1) \pi_t}] - \frac{1+\gamma}{1+\varepsilon} \pi_t - \frac{\gamma}{2} (\pi_t - 1)^2.
$$

where $T_{end} = 500$ in the simulations and the money demand function (C2)
has been used to substitute out real balances from the utility function. $\chi = 1$ is assumed as in Chapter 2.5 of (Gali 2008) and $R_{-1} = R_0$ and $y_{-1} = y_0$ is assumed for the initial period.

A comparison of the three policy regimes is now made in terms of the ranges of inflation, output and the interest rate and in terms of the probability of hitting the zero lower bound using the set of simulations for Tables 1 and 2. For the latter results we assume the ZLB is hit whenever $R$ is smaller than 1.001. Table A.1 gives the results.

</table>

Note: nog = without forward guidance and wig = with forward guidance.

It is seen that if there is no forward guidance IT appears to perform somewhat better overall than PLT or NGDP regimes. For the ranges of variables the results are close to each other, but the outcome is clear for the probability of hitting the ZLB. It is also seen that with forward guidance the results for both PLT and NGDP regimes improve, except for the output fluctuation ranges. We note that the likelihood of deflation falls under PLT and NGDP with forward guidance. The ZLB is hit in all regimes with the minimum occurrence with IT though the NGDP regime with forward guidance also fares well in this dimension.
